The experiment of the NA61/SHINE Collaboration at the CERN SPS is performing a unique study of the phase diagram of strongly interacting matter by varying collision energy and nuclear mass number of colliding nuclei. In central Pb + Pb collisions, the experiment of the NA49 Collaboration found structures in the energy dependence of several observables in the energy range of the CERN SPS that had been predicted for the transition to a deconfined phase. New measurements of the NA61/SHINE Collaboration find intriguing similarities in $p + p$ interactions for which no deconfinement transition is expected at the energies of the SPS. Possible implications will be discussed.

DOI: [10.1103/PhysRevC.102.011901](https://doi.org/10.1103/PhysRevC.102.011901)

The standard approach to heavy-ion collisions [1] assumes creation of strongly interacting matter in local equilibrium at the early stage of a collision. The matter properties depend on energy and baryon densities via an equation of state. The matter expansion is modeled by hydrodynamics and its conversion to final-state hadrons by statistical hadronization models [2–4]. The early stage energy density monotonically increases with collision energy, and, at sufficiently high energies, the state of matter is expected to change from the confined phase to the quark-gluon plasma (QGP).

In an energy scan of central Pb + Pb collisions at the CERN SPS, the experiment of the NA49 Collaboration found structures in a common narrow energy interval $\sqrt{s_{NN}} \approx 7\text{--}12$ GeV [5–7] ($\sqrt{s_{NN}}$ is the collision energy per nucleon pair in the center-of-mass system) for several observables that had been predicted [8] for the transition to the QGP phase. The most conclusive are as follows:

- (i) a fast rise and sharp peak in the ratio of strangeness to entropy production,
- (ii) a fast rise and following plateau of the temperature as measured by the inverse slope parameter of the kaon transverse mass distributions.

Experimental results on proton-proton ($p + p$) interactions served as an important reference with respect to which new physics in heavy-ion collisions was searched for. The most popular models of $p + p$ interactions are qualitatively different from the standard approach to heavy-ion collisions. They are resonance-string models [9] in which the hydrodynamic expansion of the strongly interacting matter created in nucleus-nucleus ($A + A$) collisions is replaced in $p + p$ collisions by excitation of resonances or strong fields between color charges of quarks and diquarks (strings). The assumption of statistical hadronization of matter is substituted by dynamical modeling of resonance and/or string decays as well as quark/gluon fragmentation into hadrons. Since the early days, the different modeling of $p + p$ interactions and heavy-ion collisions was supported by qualitative disagreement of the $p + p$ data with predictions of statistical and hydrodynamical models—large particle multiplicity fluctuations and a power-law shape of transverse momentum spectra at high p_T [10]. On the other hand, the different modeling has been questioned by striking agreement of the $p + p$ data with other predictions of statistical and hydrodynamical models—mean multiplicities of hadrons and transverse mass spectra at low and intermediate p_T 's follow a similar pattern. Moreover, recent data of the Large Hadron Collider (LHC) on

the azimuthal angle distribution of charged particles in high multiplicity $p + p$ interactions [11–13] show anisotropies up to now observed only in heavy-ion collisions and attributed to the hydrodynamical expansion of matter [14]. Also, it was reported that relative strange particle yields in $p + p$ interactions at the LHC smoothly increase with increasing charged particle multiplicity and, for high multiplicity collisions, are close to those in Pb + Pb collisions [15]. This suggests that strongly interacting matter may also be produced in $p + p$ interactions at energies of the LHC with sufficiently high particle multiplicity.

This Rapid Communication addresses the relation between the observation of effects possibly indicating the onset of deconfinement in Pb + Pb collisions and the recently uncovered, still unexplained, features in $p + p$ interactions.

New experimental insight is possible thanks to recent results on $p + p$ interactions at the CERN SPS from the fixed target large acceptance hadron detector of the NA61/SHINE Collaboration [16]. The measurements [17,18] cover the energy range in which experimental effects attributed to the onset of deconfinement in heavy-ion collisions are located. They allow to significantly extend and improve the world data on the K^+/π^+ ratio [19,20] and the inverse slope parameter T of transverse mass spectra of kaons [21]. Furthermore, recent data on $p + p$ interactions at energies of the LHC allow to establish the collision energy dependence of bulk hadron production properties in the energy range in which the quark-gluon plasma is likely to be created in heavy-ion collisions.

The energy dependence of the K^+/π^+ ratio at midrapidity and in the full phase space for inelastic $p + p$ interactions is shown in Figs. 1(a) and 1(b), respectively. The results for heavy-ion (Pb + Pb and Au + Au) collisions are plotted for comparison. The results on $p + p$ interactions of the NA61/SHINE Collaboration at energies of the CERN SPS are shown together with the world data [19,20,22–39]. Results on the midrapidity ratio (the top-left plot) cover the range from low energy of the SPS to the energies of the LHC. The $p + p$ data on the full phase-space ratio (the top-right plot) extends only to $\sqrt{s_{NN}} \approx 50$ GeV, whereas the heavy-ion data reach 200 GeV. The energy dependence of the midrapidity and full phase-space ratio in inelastic $p + p$ interactions is similar. This seems to be also true for heavy-ion collisions. The collision energy dependence of the K^+/π^+ ratio in heavy-ion collisions shows the so-called *horn* structure. Following a fast rise, the ratio passes through a maximum in the range of the SPS and then settles to a plateau value at higher energies.

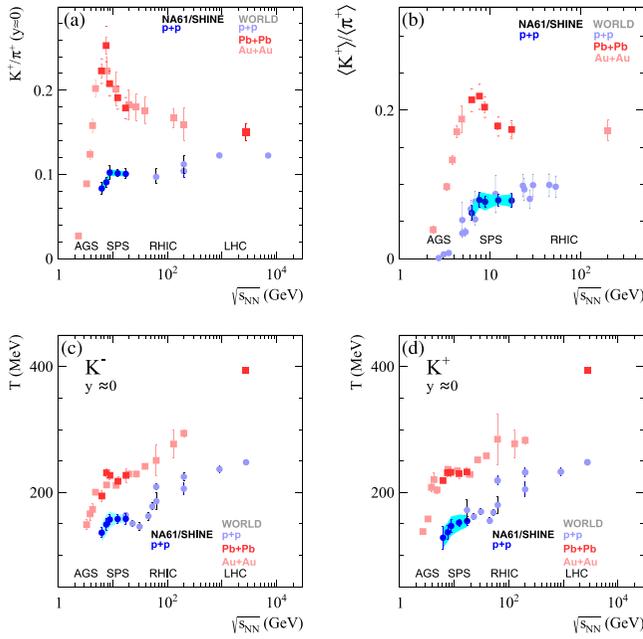

FIG. 1. Energy dependence of the K^+/π^+ ratio (a) at midrapidity and (b) in the full phase space as well as (c) the inverse slope parameter T of transverse mass spectra at midrapidity for K^- and (d) K^+ mesons. The results for inelastic $p+p$ interactions of the NA61/SHINE Collaboration (blue circles) are shown together with the world data on $p+p$ interactions (light blue circles) as well as central Pb + Pb (red squares) and Au + Au (light red squares) collisions [21,23,25–39]. The points of the NA61/SHINE Collaboration include statistical uncertainties, and the systematic uncertainties are marked as a shaded band. For the K^+/π^+ and $\langle K^+ \rangle / \langle \pi^+ \rangle$ ratios, the total uncertainties are marked for the points of the (Pb + Pb collisions) of the NA49 Collaboration, the ($p+p$, Au + Au collisions) of the STAR Collaboration, of the PHENIX Collaboration, the (Au + Au collisions) of the BRAHMS Collaboration, and the ($p+p$, Pb + Pb collisions) experiments of the ALICE Collaboration, whereas only statistical uncertainties are plotted for the remaining points. For the inverse slope parameter T of transverse mass spectra, the total uncertainties are marked for the points of the (Pb + Pb collisions) of the NA49 Collaboration, whereas only statistical uncertainties are plotted for the remaining points.

The K^+/π^+ ratio at energies of the SPS was shown to be a good measure of the strangeness to entropy ratio [7] which is different in the confined phase (hadrons) and the QGP (quarks, antiquarks, and gluons). This is because, at high baryon to meson ratio (energies of the SPS and below), the antihyperon yield is small and the main carriers of anti-strange quarks are K^+ and K^0 with $\langle K^+ \rangle \approx \langle K^0 \rangle$ due to approximate isospin symmetry in heavy-ion collisions. Thus, the K^+ yield counts about half of the strange quark-antiquark pairs ($s\bar{s}$) produced in the collisions and contained in the reaction products [7]. In contrast, fractions of strange quarks carried by K^- , \bar{K}^0 , and hyperons are comparable and change significantly with the baryon to meson ratio. At lower collision energies, relatively more strange quarks are carried by hyperons and less by antikaons. Thus, the energy dependence of the K^- yield does not follow the energy dependence of $\langle s\bar{s} \rangle$. This is illustrated

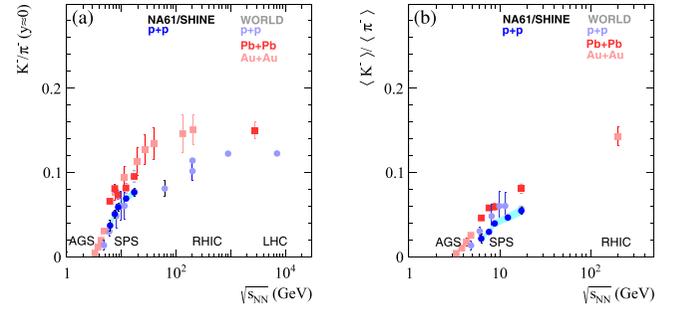

FIG. 2. Energy dependence of (a) the K^-/π^- ratio at midrapidity and (b) in the full phase space. The results for the inelastic $p+p$ interactions of the NA61/SHINE Collaboration (blue circles) are shown together with the world data on $p+p$ interactions (light blue circles) as well as central Pb + Pb (red squares) and Au + Au (light red squares) collisions [21,23,25–38]. The points of the NA61/SHINE Collaboration include statistical uncertainties, and the systematic uncertainties are marked as a shaded band. For the K^-/π^- and $\langle K^- \rangle / \langle \pi^- \rangle$ ratio, the total uncertainties are marked for the points of the (Pb + Pb) interactions of the NA49 Collaboration, the (Au + Au) interactions of the STAR Collaboration, the ($p+p$) interactions of the PHENIX Collaboration, the ($p+p$ and Pb + Pb) interactions of the ALICE Collaboration, and the (Au + Au) experiments of the BRAHMS Collaboration whereas only statistical uncertainties are plotted for the remaining points.

in Fig. 2 where the energy dependence of the K^-/π^- ratio at midrapidity (a) and in the full phase space (b) for inelastic $p+p$ interactions and heavy-ion collisions is shown. In conclusion, the K^+ yield is preferred over K^- and Λ yields when the total number of $s\bar{s}$ pairs is of interest as in the search for the QGP [40] and the onset of deconfinement [8].

The collision energy dependence of the K^+/π^+ ratio in inelastic $p+p$ interactions is different from the one in heavy-ion collisions, see Fig. 1. First of all, the ratio is smaller in $p+p$ interactions than in Pb + Pb and Au + Au collisions and does not show the horn structure.

The $p+p$ ratio approaches that in heavy-ion reactions with increasing energy, at the LHC, it is only about 20% smaller than the corresponding ratio for central Pb + Pb collisions. Starting from the threshold energy, the ratio in $p+p$ interactions steeply increases to reach a plateau at energies of the CERN SPS. The plateau is followed by a weak increase towards energies of the LHC. Notably, the beginning of the plateau in $p+p$ interactions coincides with the horn maximum in heavy-ion collisions.

According to the standard model of heavy-ion collisions, the inverse slope parameter T obtained from exponential fits of transverse mass spectra is sensitive to both the temperature and the radial flow in the final state. The energy dependence of T of the transverse mass spectra of K^+ and K^- mesons produced at midrapidity in inelastic $p+p$ interactions is presented in Figs. 1(c) and 1(d), respectively. The results of the NA61/SHINE Collaboration [17] are compared to the world data for $p+p$ and heavy-ion collisions [21,23,25–38]. Unless the T parameter was given directly by the experiment, it was taken from Ref. [21] or determined from transverse mass/momentum spectra according to the procedure of

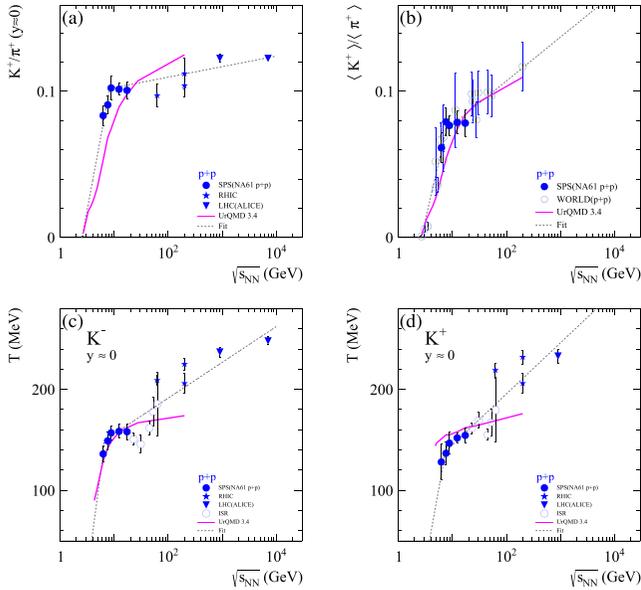

FIG. 3. Energy dependence of (a) the K^+/π^+ ratio in inelastic $p + p$ interactions at midrapidity and (b) in the full phase space as well the inverse slope parameter T of transverse mass spectra at midrapidity for (c) K^- and (d) K^+ mesons. The data are fitted by two straight lines in order to locate the position of the break in the energy dependence. The experimental results are compared with predictions of the resonance-string model Ultrarelativistic Quantum Molecular Dynamics (UrQMD) [42]. Only statistical uncertainties are plotted and used for the fit.

Ref. [21]. The collision energy dependence of the T parameter in heavy-ion collisions shows the so-called *step* structure. Following a fast rise, the T parameter passes through a stationary region, which starts at the low energies of the SPS and then (above the top energy of the SPS) enters a domain of a steady increase. The increase continues up to the top energy of the LHC. The step was predicted as a signal of the onset of deconfinement [8,41] resulting from the softening of the equation of state in the transition region. The collision energy dependence of the T parameter in inelastic $p + p$ interactions is similar to the one for central Pb + Pb and Au + Au collisions. The main difference is that the T parameter in $p + p$ interactions is significantly smaller than for heavy-ion collisions which is usually attributed to smaller radial flow.

To estimate the break energy between a fast rise at low energies and a plateau or slower increase at high energies two straight lines were fitted to the $p + p$ data (see Fig. 3). The low-energy line was constrained by the threshold energy for kaon production. The fitted break energy is 8.3 ± 0.6 , 7.70 ± 0.14 , 6.5 ± 0.5 , and 7.9 ± 0.2 GeV for the K^+/π^+ , $\langle K^+ \rangle / \langle \pi^+ \rangle$ ratios and $T(K^-)$, $T(K^+)$, respectively. These values are close to each other and surprisingly close to the energy of the beginning of the horn and step structures in central Pb + Pb collisions—the transition energy being approximately 8 GeV (see Fig. 1).

Figure 3 presents also predictions of a resonance-string model UrQMD [42]. This model assumes the transition between particle production by resonance formation at low

energies and string formation at high energies [43]—the *resonance-string transition*. The postulate allows to approximately fit the fast low-energy increase in the K^+/π^+ ratio and the inverse slope parameter of transverse mass spectra of charged kaons and its slowing down at high energies. The sharpness of the break is not reproduced by the model.

The unexpected similarity of the transition energy in central Pb + Pb collisions and the break energy in $p + p$ interactions provoke the question whether there is a common physics origin of the two effects. Is this coincidence accidental? If not, do we see effects included in standard modeling of heavy-ion collisions in $p + p$ interactions, or reversely nonequilibrium processes in $p + p$ interactions lead to the horn and step in heavy-ion collisions? The interpretation of these results is still under vivid discussion. An obstacle is that the validity of quantitative models is usually restricted to a limited range in collision energy, size of colliding nuclei and concerns only selected observables. Examples of recent developments are given in Refs. [44–49].

To summarize, new results of the NA61/SHINE Collaboration on the collision energy dependence of the K^+/π^+ ratio and the inverse slope parameter of kaon m_T spectra in inelastic $p + p$ interactions are presented together with a compilation of the world data. The $p + p$ results are compared with the corresponding measurements in central Pb + Pb and Au + Au collisions. The comparison uncovers a similarity between the collision energy dependence in $p + p$ interactions and central heavy-ion collisions—a rapid change in collision energy dependence of basic hadron production properties in the same energy range. At the same time, they confirm with higher significance previously reported striking differences between results for $p + p$ interactions and heavy-ion collisions. Possible interpretations are briefly discussed. Clearly, understanding of the origin for the similarity between results on heavy-ion collisions and $p + p$ interactions is one of the key objectives of heavy-ion physics today. Emerging results from the NA61/SHINE Collaboration (nuclear mass number)—(collision energy) scan as well as results from the LHC and the Relativistic Heavy-Ion Collider (RHIC) on collisions of small- and medium-size systems qualitatively change the experimental landscape. In parallel, significant progress is needed in the modeling of collision energy and system-size dependence which would extend the validity of models to the full range covered by the data.

We would like to thank the CERN EP, BE, HSE, and EN Departments for the strong support of the NA61/SHINE Collaboration.
