Abstract Studies concerning bat autumn swarming behavior suggest that the main purpose of this phenomenon is mating. However, the process of fat accumulation is crucial for surviving winter, and it seems to be in clear conflict with a need to strive for the opportunity to mate prior to hibernation. Investment in one activity limits the other one creating a trade-off between them. The aim of our study was to describe the activity pattern of each sex-age group (adult males, adult females, subadults) of the Natterer's bat during swarming period and to investigate the fat accumulation process of adult males in the context of their reproductive strategy. Bats were captured by mist nets at the swarming site fortnightly from the early August until the late November. The age, sex, reproductive status, and body condition index (mass to forearm ratio, BCI) were recorded. The activity peak of both sexes, adults, and subadults was observed in the late September. That time in season, BCI of adult males was the lowest, and there was no

correlation between the hour of an adult male capture and its BCI value within one night ($r_s = 0.23$; $p = 0.157$). Such correlation was observed later in the season (early October: $r_s = 0.44$; $p = 0.020$; late October: $r_s = 0.48$; $p = 0.002$). A negative correlation between adult males' BCI and proportion of adult females was found ($r = 0.44$; $p = 0.000$). We conclude that the activity peak of females is likely to be responsible for the effort of the mating behavior of the males, which is reflected by their low condition index. We suggest that the gleaning foraging strategy of Natterer's bat allows the males to postpone their fat accumulation until just before hibernation.

Introduction

The term “swarming,” with regard to the temperate zone bats, was described as an increase in bat activity in front of the hibernacula, before the hibernation period. It appeared in the 1960s and referred to the behavior of *Myotis lucifugus* (North America) (Fenton 1969). At that time, the explanation for this activity was presented as a combination of three main hypotheses: mating, familiarizing juveniles with accessible wintering sites, and the final arrival of bats to the hibernacula. To date, results of genetic surveys suggest that mating is the main purpose of swarming (Kerth et al. 2003; Furmankiewicz and Altringham 2007; Bogdanowicz et al. 2012). It is suggested that the Natterer's bat is one of several European species mating during swarming (Rivers et al. 2005). This species exhibits similar behavior to other swarming bats performing chasing flights with social calls (Trappmann 1997; Rivers et al. 2005). Because swarming activity of most temperate bats occurs in autumn, it is in strong

conflict with the necessity of fat accumulation for hibernation. It means that a bat has to compromise between spending time and energy on both activities, because an individual success (survival and reproduction) depends on the effect of proper investment. Males usually outnumber females during the entire swarming season (Rivers et al. 2006; Gottfried 2009; Piksa et al. 2011). This is interpreted as males spend more time at swarming sites than females to increase the number of copulations, which enhances their reproductive success (Rivers et al. 2006). Temperate bat species vary in their foraging techniques and often use different food resources. Feeding strategy may influence bat behavior, such as emergence time, night activity peaks, and commuting to feeding grounds, especially when weather conditions deteriorate. Species efficiency of food resources exploitation may be crucial in fat accumulation strategy before hibernation. Bat species differ in timing of their activity peaks in the swarming season, which lasts from the middle of summer to the late autumn (Furmankiewicz and Górnjak 2002; Parsons et al. 2003; Piksa et al. 2011). An explanation of the late activity peak of the Natterer's bat proposed by Parsons et al. (2003) was its gleaning strategy, which makes foraging activity independent of low air temperature.

The Natterer's bat has not yet been studied in the context of the autumn fat accumulation strategy, especially on the background of energy-consuming swarming behavior. The aim of this study was to describe the activity pattern of sex-age groups of this species and to investigate the autumn fat accumulation strategy of males. As the consequence of the trade-off between reproduction success in mating and survival during hibernation, we expect:

1. prolonged activity of adult males in season in comparison to subadults and adult females
2. negative relation between the BCI value of adult males and the proportion of adult females
3. late fat stores buildup of adult Natterer's bat males relating to the species foraging strategy

Material and methods

Study area

The study was carried out in the Ciężkowickie Foothills, Skamieniałe Miasto Reserve in southern Poland (N 49° 46' 39"; E 20° 57' 56") (Fig. 1). This area is a mosaic of different habitats such as cropland, grassland, wasteland, buildings, rivers, and patches of forest. The reserve was primarily created to protect sandstone rock formations and is mostly covered by a deciduous forest with well-developed undergrowth. Altogether 38 caves have been described in the Ciężkowickie Foothills to date (Klassek and Mleczek 2014), thirteen of them are located within

the Skamieniałe Miasto Reserve. Three largest caves situated on the same slope of the gorge were selected for research: Skamieniała Cave (20-m length, 9-m denivelation), Pajęczka Cave (9-m length) and Krótka Cave (10-m length) (Mleczek 1997). Other caves in the reserve are only small niches in the rock formations (Fig. 1).

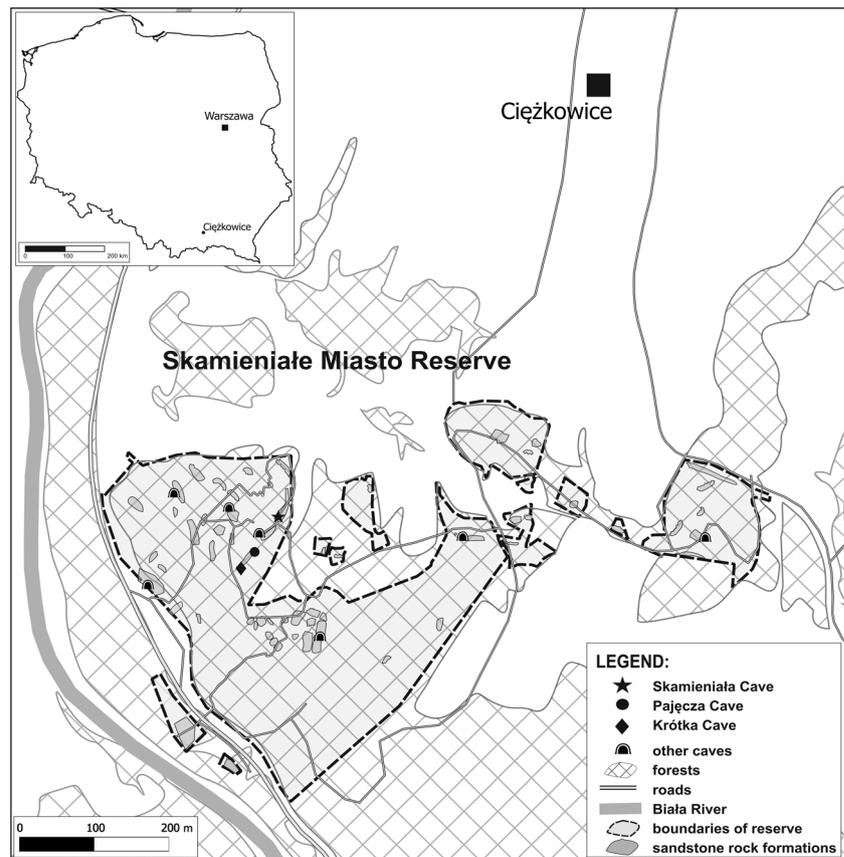

Material and methods

The mist netting was carried out fortnightly from the beginning of August until the end of November in 2009 and 2010. Bats were caught using mist nets (Ecotone, Poland) in front of three caves: Skamieniała, Pajęczka, and Krótka (mist nets partially covered the entrances). The catches were carried out on nearly the same dates of the two seasons. They began at dusk and lasted from 6 to 10 h, until bat activity ceased. The species, sex, and reproductive status of the captured bats were identified in order to determine the swarming activity pattern of each sex-age group of the Natterer's bat (adult males, adult females, subadults). The age was determined by the degree of the ossification of the epiphyseal joints in the finger bone bases and by other auxiliary traits like pelage color or degree of tooth wear (Racey 1974; Anthony 1988; Schick et al. 2003; Haarsma 2008). If there was any doubt, the bat was classified as subadult. Measurements of right forearm length [mm] and body mass [g] were taken and the time of capture was noted to estimate the condition of captured bats both for the time in season and night. A non-toxic color alcohol marker was applied on a bat's back between blades to avoid double measurements of the same individual. The bats were released at the site of capture immediately after the measurements were completed.

Statistical analysis

The data from both years were pooled to increase the sample size. The body condition index (BCI) was applied as the estimator of a bat's condition, which is defined as body mass to forearm ratio [g/mm] (Speakman and Racey 1986). One-way ANOVA was performed to test the differences of the mean values of BCI of the Natterer's bat adult males between the nights in season. The Box-Cox transformation was applied to normalize the data distribution. The homogeneity of variance was confirmed by means of Levene's test. A post hoc Tukey's test for unequal numbers for assessing the significance of any differences between the catches was performed. This analysis was conducted to check the changes in BCI between nights in the swarming season to estimate when the fat reserve buildup for adult males starts. The relationship between bats' BCI and the subsequent hours (1 h interval) of the night was tested using Spearman's rank correlation. For these analyses the sunset hour was the zero hour. Three consecutive nights on which there were sufficient numbers of adult males (starting from the

Fig. 1 Study area, Skamieniałe Miasto Reserve, southern Poland, with forest cover, location of sandstone formations, caves and mist-netting sites

activity peak night) were analyzed, while only the activity peak night was analyzed for adult females and subadults. These analyses were conducted to test if the nights of the highest activity are spent on feeding, which would be seen in positive correlation between bats' BCI and the consecutive hours of the night. The relationship between adult males' BCI and proportion of females caught per night was analyzed using Pearson's correlation to test if the higher proportion of females affects negatively the males' BCI values. Data analyses were performed using STATISTICA 10.0.

Results

The Natterer's bat swarming population activity and structure (sex-age groups)

The Natterer's bat was the dominant species within the swarming season (55.1 % of the entire season, 77.3 % at the peak of the swarming activity). Because of absence of this species in the beginning of August, only 14 nights were analyzed. Within all sex-age groups, during both years, the adult males predominated (145 males, 29 females, 32 subadults altogether) (Table 1). The adult male to female ratio changed during the season, but males always outnumbered females: for

the whole period studied it was ca. 5:1 (83.3 % for adults only, 81.5 % including subadults). Sexually active adult males (swollen cauda epididymides) constituted 88.6 % of all of the captured adult males. Adult males and subadults were present throughout the whole season while adult females were not. The peak of activity of adult females and subadults overlapped. It occurred in late September and was also the species activity peak. Adult males had relatively high level of activity from late September to late October (Fig. 2a). Adult males and females showed different activity patterns which were constant in both years (Fig. 2b).

The body condition index (BCI) of the Natterer's bat swarming population

One-way ANOVA followed by Tukey's post hoc test revealed differences between individual nights regarding adult males' BCI ($F_{(6, 130)} = 17.80, p = 0.000$). The lowest mean BCI value of the adult males was observed at the time of the peak activity of the adult females. Later in season, the BCI values of the males increased (Fig. 2c). At the peak of swarming activity (late September), there were no changes in BCI during the night (adult males: $r_s = 0.23, p = 0.157$; adult females: $r_s = 0.32, p = 0.177$; subadults: $r_s = 0.36, p = 0.193$). In contrast, positive and significant changes in males' BCI were observed during the next two

Table 1 Total number of the Natterer's bats captured during the autumn swarming season in Skamieniałe Miasto Reserve (fortnightly, a 2-year study)

	Aug_1	Aug_2	Sept_1	Sept_2	Oct_1	Oct_2	Nov_1	Nov_2
Adult males	0	10	4	38	29	40	18	6
Adult females	0	3	0	18	6	0	2	0
Subadults	0	2	1	17	8	1	2	1
Total	0	15	5	73	43	41	22	7

nights (not enough data to analyze adult females and subadults). In early October, the correlation was moderate ($r_s = 0.44$,

$p = 0.020$), and became stronger in late October ($r_s = 0.48$, $p = 0.002$). Negative and significant correlation of adult males BCI value and proportion of females caught per night was observed during season ($r = -0.44$, $p = 0.000$).

Discussion

The swarming activity patterns of three sex-age groups of the Natterer's bat

The swarming activity pattern of the Natterer's bat in the Skamieniałe Miasto Reserve, with relatively late maximum (late September), resembles that reported from a bat hibernacula in Poland (Furmankiewicz and Górnica 2002; Piksa 2008; Piksa et al. 2011), but also in Latvia (Šuba et al. 2008) and UK (Parsons et al. 2003; Rivers et al. 2006; Glover and Altringham 2008). Adult individuals prevailed over young bats as in other studies (Furmankiewicz and Górnica 2002; Glover and Altringham 2008; Piksa 2008; Gottfried 2009). The high male ratio: 81.5 % (subadults included) and their reproductive status (88.6 % sexually active) is also comparable with other swarming sites of the Natterer's bat in Poland and UK (Furmankiewicz and Górnica 2002; Rivers et al. 2006; Glover and Altringham 2008).

Our studies confirmed some earlier observations on sex-age group activity patterns, e.g., the proportion of females (adults and subadults pooled) increased in late September (at the species activity peak) and, in contrast to males (adults and subadults), females visited the swarming site less frequently and relatively shorter in season than males (Rivers et al. 2006; Glover and Altringham 2008). The shorter presence of adult females in comparison to adult males is consistent with the different trade-off between mating and foraging for these sex-age groups. Males do not contribute to raising their offspring. Therefore, they should spend more time and energy at swarming sites than females to increase the number of copulations (inseminated females), which increases their reproductive success (Rivers et al. 2006). In contrast, reproductive success of females depends on saving as much fat reserves as possible to the end of hibernation in order to enter gestation in good body condition (Kunz et al. 1998; Jonasson and Willis 2011). In consequence, for females, it is profitable to reduce the number of copulations and energy spent on mating.

Studies of the Natterer's bat in the Skamieniałe Miasto Reserve revealed that the activity peak of adult females overlaps with activity peak of subadults, as it has been earlier observed for two other swarming species *Myotis mystacinus* and *Myotis daubentonii* (Piksa 2008; Šuba et al. 2008). Our observation corroborates the hypothesis that subadult bats come to swarming sites following mothers or female relatives from the same nursery colony (Furmankiewicz 2008; Piksa 2008). For the young of the year, it is crucial to gather as much information about the home area as possible, e.g., to know where their conspecifics gather for mating and/or hibernation. However, because most of temperate insectivorous bats are reproductively active in the second year of life, in the case of subadults, reproduction versus fat accumulation trade-off in autumn is highly skewed towards completing fat reserve storage for winter (Kunz et al. 1998; Encarnação et al. 2006). Especially that for young, inexperienced bats, foraging probably requires greater effort than for adults.

Comparing the three mentioned sex-age groups the trade-off between reproduction and autumn fat accumulation generates the greatest conflict for adult males. One may expect that males should monitor the swarming site constantly to increase the probability of mating and at the same time should keep on foraging to build up the fat reserves for hibernation. To check whether this hypothesis is valid for the Natterer's bat males, we followed BCI changes in this group.

Condition of adult males of the Natterer's bat in relation to presence of adult females

Our data allowed to analyze and therefore to discuss in detail the BCI changes within the entire swarming season for adult males only. In case of females, the BCI changes were analyzed only at their peak of activity (late September). The body condition of adult males and females during the maximum activity night did not change in time, which means that both sexes did not forage intensely then. Furthermore, the males' BCI value was the lowest at the peak of adult females' activity and was negatively correlated with the proportion of adult females in the entire swarming season. Contrary, in consecutive hours of the nights of no or low activity of females (early October or late October), the males' BCI value was slightly growing. It suggests that adult males in the presence of females reduce foraging and focus on mating, while in the rest of the season these proportions are reversed.

Although the data concerning the changes of body condition of swarming populations is scarce, we observe that the Natterer's bat BCI changes pattern is consistent with other species taking part in this phenomenon. In *Barbastella barbastellus* during the period of the most intensive swarming activity, both adult females and adult males have the lowest BCI in season (Gottfried 2009). In *M. daubentonii*, the lowest body mass of adult males in swarming season overlaps with the swarming

activity peak of adult females as well (Encarnação et al. 2004; Šuba et al. 2008; Rughetti and Toffoli 2014). Similarly, the short period of lowering the body mass of males of *Plecotus auritus* in autumn was interpreted as their mating effort (Entwistle et al. 1998). The compilation of results of studies relating to the swarming populations of *M. daubentonii* and *M. mystacinus* or *Myotis brandtii* indicates that adult males of these species seem to spend on foraging only the nights with low proportion of adult females (Piksa 2008; Šuba et al. 2008, 2011).

The BCI changes analyzed on the background of activity patterns of the latter three species indicate that for them the main period of fat accumulation occurs before the females' activity peak, i.e., before mating. Our results suggest that the Natterer's bat strategy is different.

Late fat reserve buildup of adult males of the Natterer's bat in relation to foraging strategy

In our study, the Natterer's bats appeared at the swarming site not earlier than late August. The adult males' seasonal and nightly BCI changes indicated that their fat accumulation for winter starts in October, after the species' peak of activity, and lasts nearly just before hibernation period. It was mentioned before that the peak of activity of the Natterer's bat occurs later in comparison to other swarming species such as: *M. brandtii*, *M. mystacinus*, *M. daubentonii*, *Myotis dasycneme*, and *B. barbastellus* (Furmankiewicz and Gómiak 2002; Parsons et al. 2003; Piksa 2008; Šuba et al. 2008; Gottfried 2009). This late swarming activity was suggested to be coupled with the Natterer's bat's greatest gleaning ability (Parsons et al. 2003). British authors suggested, on the basis of results obtained by Barclay (1991), that gleaning could be beneficial during cold swarming nights in autumn. Indeed, diet of the Natterer's bat may consist of up to 70 % of non-flying prey (Shiel et al. 1991; Andreas et al. 2012a). It was shown that for temperate bats of aerial hawkers, the food availability in October decreases to one quarter or even one tenth in comparison to its greatest abundance in July and August (Speakman and Rowland 1999). In fact, bats with the early swarming peak of activity forage mainly on flying prey (Flavin et al. 2001; Pithartová 2007; Lučan et al. 2009; Krüger et al. 2012; Andreas et al. 2012b; Nissen et al. 2013).

In the case of aerial hawkers and trawlers, the time for effective foraging in autumn seems to be shorter than for gleaners, and in consequence, the fat accumulation for those guilds starts earlier in the season, at flying prey activity peak. This regularity can be seen when comparing our results with the body mass seasonal changes of *M. daubentonii* adult males from the male colonies or loners (not swarming population) (Encarnação et al. 2004; Rughetti and Toffoli 2014). The body mass of *M. daubentonii* males is constantly growing from early August until early September, while our data shows that the Natterer's bat BCI starts to grow in late September achieving the highest value in late November, just before hibernation. Although *M. daubentonii*

can use trawling (=gaffing) strategy which allows to collect prey from the water surface (Jones and Rayner 1988; Siemers et al. 2001), this feeding strategy has other constraints. It was observed that *M. daubentonii* activity time above the water is negatively affected by fog (Ciechanowski et al. 2007). In autumn, fog above the water bodies is more frequent than in summer. Thus, again, it seems to be more beneficial for trawling bats to accumulate most of their winter fat reserves earlier in the season. Our interpretation of differences in fat accumulation strategies between these guilds is reinforced by the latest surveys concerning the Natterer's bat and *M. daubentonii*. The energy budget balance in *M. daubentonii* shows that males of this species use combination of metabolic compensation and daily torpor in autumn to compensate for the low food availability, opposite to active food intake earlier in the season (Becker et al. 2013). In contrast, the Natterer's bat is able to forage effectively even in winter (Hope et al. 2014). Based on the results obtained in our work and cited literature data, we suggest that the Natterer's bat may simply postpone the active food intake (building fat reserves) in the swarming season to late autumn.

Conclusions

Our results revealed that adult females and subadults are mainly responsible for the swarming activity peak of the Natterer's bat (late September). Adult males visit the swarming site longer in the season than adult females, which supports the interpretation of this behavior as increasing the reproductive success of males (Rivers et al. 2006). The data collected in Skamieniałe Miasto Reserve showed that BCI values of adult males and adult females of the Natterer's bat were the lowest at the night of the species' activity peak and did not increase in consecutive hours of that night. Later in the season, when adult females were less numerous or absent (subadults only), the BCI value of adult males started to increase, both: in season and in night. It suggests that adult males of the Natterer's bat spend most of the night of their maximum swarming activity on mating, and postpone foraging and fat accumulation until after the mating. Our observation is in consent with an earlier premise regarding foraging strategies of temperate bats (Parsons et al. 2003; Becker et al. 2013): males of aerial hawkers and aerial hawkers and trawler guilds have to build up most of their winter fat reserves before mating when the flying prey is more abundant, while gleaners as the Natterer's bat can postpone fat accumulation by active food intake even just before hibernation.

Acknowledgments We would like to thank students from the Student Naturalist Society of Jagiellonian University (KPStUJ) for actively participating in the surveys, Paweł Kozioł and Dagmara Klimczok from RDOŚ in Tarnów for their assistance in the field, and Wojciech Sanek from the Natural Science Museum in Cieżkowice for offering us accommodations. We are also grateful to Elżbieta Małkowska for help with the artwork.
