Abstract

Purpose: Lymphoproliferative neoplasms are the largest and most frequently diagnosed entities in the group of haematological malignancies. The aim of the study was to assess whether apparent diffusion coefficient (ADC) measured on the first day of the second cycle of chemotherapy could be a predictor of prognosis and of the final treatment’s outcome.

Material and methods: The study included 27 patients with diagnosed Hodgkin’s and non-Hodgkin’s lymphoma, who had magnetic resonance (MR) performed with diffusion weighted imaging/apparent diffusion coefficient (DWI/ADC) before and on the first day of the second cycle of chemotherapy. Imaging was performed using a 1.5 T MR scanner. ADC was measured in lymphoma infiltration in the area of the lowest signal in the ADC map and the highest signal on b 800 images in post-treatment study. After that, the corresponding area was determined in a pre-treatment study and an ADC value was measured.

Results: The difference between ADC values in pre-treatment (ADC = 720 mm²/s) and post-treatment (ADC = 1059 mm²/s) studies was statistically significant (p < 0.001). Cutoff values for estimating response to treatment were established at the level of ADC 1080 mm²/s, and ADC to muscle ratio at 0.82 in post-treatment study. Patients with ADC > 752 mm²/s before treatment manifested lower probability of progression than patients with ADC < 752 mm²/s.

Conclusions: ADC measurement’s before treatment and on the first day of the second cycle of chemotherapy can be used as a prognostic marker in lymphoma therapy. ADC values lower than 1080 mm²/s and an increase of the ratio after the treatment can be considered as a marker of disease progression.

Key words: lymphoma, Hodgkin’s lymphoma, magnetic resonance imaging, diffusion MRI.

Introduction

Lymphoproliferative neoplasms are the largest and most frequently diagnosed entities in the group of haematological malignancies [1] staging, and response assessment of patients with Hodgkin lymphoma (HL). Over the years an increasing trend of incidence rate of lymphomas has been noticed. Currently it amounts to approximately 20–22 new cases per 100,000 persons per year, according to various registers [2, 3].
Introducing new diagnostic tools to everyday practice allows more precise evaluation of disease. One of the most important aspects is the evaluation of response to treatment. Accurate assessment of early response is crucial to the diagnosis of lymphoma. This allows patients to be distinguished within the high-risk groups and to modify ineffective treatment in the early stages. This is of utmost importance in the context of individualisation and optimisation of treatment, contributing to positive effects for both the patients and for the entire health care system (economic effect).

Positron emission tomography computed tomography (PET/CT) scanning is currently considered to be the reference method for the assessment of response in the majority of lymphomas, especially in the evaluation of early response to treatment in HL [4] who underwent both [18F]-FDG-PET/CT and whole-body MRI (including T1- and diffusion-weighted sequences). There are several studies describing the potential role of diffusion weighted imaging (DWI) in the diagnosis and evaluation of response to treatment of lymphomas [5].

The purpose of this study was the assessment of the DWI/ADC imaging protocol in the evaluation of the early response to treatment of Hodgkin’s and non-Hodgkin’s lymphomas. Additionally, we analysed whether the ADC measured on the first day of the second cycle of chemotherapy could be a predictor of prognosis and of the final outcome of the treatment.

Material and methods

The study included the final group of 27 patients with Hodgkin’s and non-Hodgkin’s lymphoma diagnosed (Table 1). They underwent MRI of the area in question before the treatment and on the first day of the second cycle of chemotherapy. All examinations were performed using a 1.5 T MR unit with a conventional phased array body coil. The DWI was performed using a standard protocol, namely the single-shot spin-echo-planar imaging (EPI) in the axial plane, with the following parameters: TR 5200-6000 ms, TE – 72 ms, voxel size 2 × 2 × 5, Bw 1448 Hz/px, b values 50, 400, and 800, 30-45 slices, duration ~6 min.

ADC maps were calculated with a dedicated workstation. ADC values were measured in lymphoma infiltration in the area of the lowest signal in the ADC map images in post-treatment study, paying particular attention to avoid areas that could affect the DWI signal, e.g. haematomas. The corresponding area was determined in the pre-treatment study, and the pre-treatment ADC values were measured afterwards. Only oval-shaped ROIs were used to measure the ADC values, and the size thereof was adjusted to the size of the area with the lowest ADC signal. The ADC values were analysed as an independent value and as a ratio – dorsal muscles were used as the reference organs (Fig. 2). A Wilcoxon test was performed to verify the difference between the ADC values before and after the treatment. The ROC curve was used to determine the cut-off values, and the odds ratio was calculated.

Results

There was a statistically significant difference between the ADC values in the pre-treatment (ADC = 720 mm²/s) and post-treatment (ADC = 1059 mm²/s) studies (Fig. 3). The ADC value increased significantly in both groups (Table 2, Fig. 4). In the group of patients with diagnosed HL the ADC increased by 344 mm²/s on average, and by 206 mm²/s in patients with non-Hodgkin’s lymphoma, respectively. The cut-off values used for estimation of the response to the treatment were established at the level of ischaemic stroke or in the evaluation of breast or prostate gland abnormalities. Numerous recent studies associated with DWI have focused on utilisation of its tools to evaluate response to treatment in oncological patients. Haematological diseases seem to be a very perspective area for the DWI tools, e.g. due to high cellularity of lymphoma infiltration [7].

The applicability of DWI has been confirmed e.g. in the detection of ischaemic stroke or in the evaluation of breast or prostate gland abnormalities. Numerous recent studies associated with DWI have focused on utilisation of its tools to evaluate response to treatment in oncological patients. Haematological diseases seem to be a very perspective area for the DWI tools, e.g. due to high cellularity of lymphoma infiltration [7].
of ADC 1080 mm$^2$/s, and the ADC to muscle ratio 0.82 in the post-treatment study (Fig. 3). The patients with ADC > 752 mm$^2$/s before treatment demonstrated lower probability of progression than the patients with ADC < 752 mm$^2$/s ($p = 0.046$). Considering the changes between the studies, an increase of the ADC by 34.5% and an increase of the ratio of by 32.5% were determined as the cut-off values. The highest odd ratios were calculated proving that the pre-examination ADC or the ratio itself would serve best for an assessment of the low response risk.

**Discussion**

Advanced imaging techniques play an important role in the diagnosis, evaluation, and staging of lymphomas [1] staging, and response assessment of patients with HL. Despite the fact that the sensitivity and specificity of PET/CT with $^{18}$F-FDG depends on the histological lymphoma subtype, the Lugano classification of malignant lymphomas recommends the use of PET/CT with $^{18}$F-FDG as the reference imaging technique combined with bone marrow biopsy (BM) [1, 8] staging, and response assessment of patients with HL. There are several studies describing the role of whole-body MRI, with the DWI/ADC measurement as a diagnostic tool in the evaluation of patients with lymphoma [9-12] metabolic tumor volume (MTV). The potential role of the measurements of DWI/ADC in patients with non-Hodgkin’s lymphoma was well described in 2012 by Chen and Zhong. The authors reported that WB-DWI can be adopted to detect morphological changes of lesions, but moreover it provides important functional information about the growth and decline process of tumour cells [13]. The effectiveness of PET-CT and MRI DWI/ADC in the initial stages of malignant lymphoma was analysed in another study. The authors compared these two methods in a pretherapeutic context and agreement for Ann Arbor staging. They reported high repeatability and agreement of MRI DWI/ADC with PET-CT [14]. Different results were stated by investigators from Finland. Wu et al. indicated superiority of the measurements of the standardised uptake value (SUV) of 2-deoxy-2-[18F]fluoro-D-glucose ($^{18}$F-FDG) against DWI/ADC in patients with diffuse large B-cell lymphoma and follicular lymphoma. There were weak inverted correlations between the SUV$_{max}$ and ADC$_{min}$ in all cases, but it was not repeated in subgroups [9] MTV. The prognostic feature of the DWI/ADC was the subject of the study performed on the group of 28 patients with primary central nervous system lymphoma. It was investigated which DWI/ADC rank or parameter is a better biomarker of the response to treatment. It was revealed that DWI/ADC 5th percentiles are good predictors for progression-free survival.

The early response to treatment is an important indicator of a patient’s condition and prognosis [15]. Appropriately quick assessment enables modification of the treatment protocol and if necessary adjustment to patient’s needs. In this study we evaluated weather the ADC measured on the first day of the second cycle of chemotherapy could be a predictor of prognosis and of the final
treatment’s outcome. There was a statistically significant difference between the DWI/ADC values in groups with Hodgkin’s and non-Hodgkin’s lymphomas. Patients with HL had higher values of DWI/ADC before and after the treatment (respectively, \( p = 0.027 \) and \( p = 0.029 \)). Similar results were obtained in other studies \[1, 16, 17\] i.e., indolent versus aggressive lymphoma, and also to assess the prognostic value of different quantitative parameters of whole-body. Our results indicated that patients with ADC > 752 mm\(^2\)/s before treatment demonstrated lower probability of progression than the patients with ADC < 752 mm\(^2\)/s (\( p = 0.046 \)). Mosavi et al. similarly reported a significant relationship between higher mean ADC and longer overall survival (\( p = 0.006 \)) \[16\]. An increase of the ADC by 34.5% after the second cycle of chemotherapy correlates with a better prognosis. This result has not been confirmed in other cancers. Multivariate analysis in head and neck cancer revealed that lower pre-treatment ADC was associated with a better response to treatment \[16\].

There were some limitations to this pilot study, such as the small number of patients with diagnosed non-Hodgkin’s lymphoma, or lack of histopathological results.
Moreover, a whole-body MRI was not available at the time of examination and MRI was performed only within the range of interest.

**Conclusions**

Measurements of the ADC values before treatment and on the first day of the second cycle of chemotherapy can be used as a prognostic marker in the therapy of lymphomas. The most promising tool for assessing response to treatment seems to be the ratio between the ADC value measured in the area of infiltration and the ADC value of the reference organ (in our case – dorsal muscles). We calculated that an increase of the ratio lower than 32.5% could serve as a poor prognostic factor and could lead to modification of treatment. Early DWI/ADC measurements enable shortening of the diagnostic process, thus obtaining a quicker assessment of prognosis. An early response to treatment can influence further therapy and can potentially increase the chances for regression of lymphoma. The results seem to be promising, but further studies with larger groups of patients and long-term follow-up are essential to prove the usefulness of the DWI/ADC measurements in the evaluation of lymphoma.
